**Abstract:** The volume of data transmitted over networks has significantly increased in recent years. For that reason, safeguarding the privacy, authenticity, and confidentiality of specific data is imperative, necessitating a type of encryption; symmetric encryption, known for its computational efficiency, is ideal for securing extensive datasets. A principal component within symmetric key algorithms is the substitution box (S-box), which creates confusion between plaintext and ciphertext, enhancing the security of the process. This paper proposes a fashion method to create chaotic S-boxes using the Rössler attractor as a chaotic process and the Rijndael S-box as a permutation box. The proposed S-boxes are evaluated with bijectivity, non-linearity (NL), strict avalanche criterion (SAC), bit independence criterion (BIC), linear approximation probability (LAP), and differential uniformity (DU). The analyses show that the proposed method helps generate a high-resistance S-box to well-known attacks and high efficiency, executing in short computational time.

## 1. Introduction

Data are present daily within our activities like instant messaging, use of social networks, online payments, health monitoring devices usage, etc. Due to the intense popularity of fields related to information and enormous amounts of it, like big data or deep learning, companies have started collecting as many details as possible about every task that could be automated or data providing insights about the company itself and its improvement opportunities [1,2]. To collect the data, it is crucial to transmit them through a network and store them remotely. Along this collection path, information is vulnerable to cyberattacks, which can result in the leaking of private data. To prevent the exposition of sensible information and keep its privacy, laws [3,4] and regulatory organizations [5] have been established. Nevertheless, they do not provide real-time security; they are only helpful in punishing the violating privacy action once it has been done. Here is where one of the most essential security tools plays an important role: cryptography.

Cryptography is the science that encompasses the principles, tools, and techniques used to alter data, intending to conceal their meaning, safeguarding against unauthorized access, or averting undetected alterations [6]. Cryptography plays an essential role in digital communications and computational aspects, primarily because of the escalating number of cyberattacks, which have been growing at 15% year over year, leading to significant financial losses, reputational damage, and disruptions in operations [7].

When talking about cryptography, we mainly have two kinds of cryptography algorithms: symmetric and asymmetric. Symmetric cryptography is based on a single shared secret to encrypt and then share data between parties. It is called symmetric because the same secret is used to encrypt and decrypt the data. Some advantages of symmetric

algorithms are they are easy to implement, they are faster than asymmetric algorithms, and when using the correct algorithm, symmetric encryption is at least as secure as asymmetric methods [8].

A fundamental component in symmetric cryptographic algorithms resides in the substitution box (S-box). S-boxes play a crucial role by introducing non-linear processes, confusion, and other properties that collectively increase the robustness of the algorithms against various types of attacks [9]. To strengthen S-boxes' non-linearity and prevent cryptanalysis [10], it is usual to include chaotic systems in their design.

A chaotic system is a concept describing the apparent randomness and irregularity within deterministic systems, where its behavior is characterized by a lack of predictability, sensitivity to initial conditions, and complex, intricate patterns of motion [11]. Due to these characteristics, including them in the S-boxes' design is often suitable. With previous properties in mind, this paper proposes a novel S-box design using a chaotic system called the Rössler attractor. Our contributions in this work are:

1. The design of an S-box incorporating the Rössler attractor.
2. A comparison of our designed S-box versus other methods, showing its effectiveness in non-linearity, strict avalanche criterion, bit independence criterion, differential uniformity, differential approximation probability, and, finally, in lineal approximation probability.
3. Creating dynamic S-boxes for symmetric algorithms by specifying certain key properties as initial conditions.

The remainder of this paper is organized as follows: Section 2 introduces the related work in the past few years and describes the required concepts to propitiate a better understanding. Sections 3 and 4 describe our proposed method and the results obtained, respectively. An analysis and a discussion about our method are provided in Section 5; also, we give our conclusions.

## 2. Background and Methods

In this chapter, we delve into the fundamental building blocks of our study on S-boxes. We provide a background, offering insights into the preliminaries necessary to understand S-boxes.

### 2.1. Related Work

Numerous researchers have explored using chaotic systems to generate cryptographic tools, including S-boxes, cipher algorithms, and HASH functions [12]. This endeavor aims to enhance the security of data transmission across networks. Furthermore, there are several methods available for their development, such as chaotic maps [13–15], Lorenz equations [16,17], and cellular automata [17,18], among others.

In [19], a novel key-dependent S-box is introduced and constructed through the iteration of continuous chaotic maps. The authors demonstrated that this S-box offers a substantially expanded key space compared to existing key-dependent chaotic S-boxes. Similarly, in [20], a method is proposed based on a piecewise linear chaotic map (PWLCM) incorporating optimization conditions. This approach effectively mitigates the linear propagation of information within a cryptosystem, consequently reducing the high differential probability encountered during the differential cryptanalysis of an S-box. Highly dispersive S-boxes are a sought-after component in cryptosystems, serving as non-linear confusion sub-layers to bolster resistance against modern attacks. For instance, Attaullah et al. introduced a scheme to create an S-box with a robust arithmetic foundation [21]. This construction relies on the group action of a projective general linear group on units of a finite local ring, aligning its attributes with those of other S-boxes. Additionally, Zahid et al. proposed an innovative technique involving cubic fractional transformation (CFT) to construct substitution boxes [22]. The cryptographic power of these S-boxes underwent rigorous assessment. In a similar vein, these authors in 2021 [23] introduced a method incorporating a square polynomial transformation, coupled with an affine transformation

and a permutation approach, to devise dynamic S-boxes. Moreover, they presented an approach utilizing a novel linear trigonometric transformation to develop dynamic and key-dependent S-boxes [24]. Thorough performance and comparative analyses underscore the S-boxes' profound efficacy for application in symmetric ciphers. On the other hand, image encryption is an efficient and vital means of safeguarding classified and confidential images. However, with the advancement of computer processing power, encryption methods such as AES, DES, or chaotic series, which were once considered secure, are now less robust [25].

Bearing that in mind, development is highlighted in [26], where an encryption algorithm employing a chaos-based S-box is devised for efficient and secure image encryption. Initially, a chaos-based random number generator is crafted by applying the suggested chaotic system. Evaluation of test outcomes attests that the proposed image encryption algorithm excels in both security and speed for diverse image encryption applications. Furthermore, Khan et al. introduced a dynamic S-box-based watermarking scheme in [27]. A piecewise linear chaotic map generates a  $16 \times 16$  dynamic substitution box (S-box), enabling the extraction of the original image at the recipient's end without compromising sensitive information. The scheme's resilience, efficiency, and security are substantiated through several assessments, including the structure similarity index, structure dissimilarity index, structure content, mutual information, energy, entropy, correlation tests, and comprehensive analysis of classical attacks. In addition, Ref. [28] presents an innovative approach centered on inverses and permutations, allowing for the easy construction of numerous highly non-linear S-boxes with minimal alterations to transformation parameters. Furthermore, an image encryption algorithm was introduced, utilizing the generated S-box to execute pixel shuffling and substitution, enhancing its statistical robustness and differential encryption capabilities.

In the realm of substitution, modern block ciphers leverage one or more substitution boxes (S-boxes), making runtime efficiency a pivotal consideration. In [29], a novel S-box was crafted using a 1D logistic map chaotic system. The chaotic sequence derived from the 1D logistic map was harnessed to produce hexadecimal code values, which were subsequently used in the construction of the new S-box. The algorithm passes all statistical tests executed in a few milliseconds.

Finally, cellular automata (CA) represents an interesting approach for designing substitution boxes (S-boxes) due to having good cryptographic properties and low implementation costs. In 2017, ref. [30] introduced the concept of evolving cellular automata rules that can be translated into S-boxes. With it, it was possible to find optimal S-boxes for sizes from  $4 \times 4$  to  $7 \times 7$ . Building on this foundation, furthermore, Mariot et al. [31] have systematically investigated the cryptographic properties of S-boxes defined by CA, proving some upper bounds on their non-linearity and differential uniformity. In particular, they propose a "reverse engineering" method based on De Bruijn graphs to determine whether a specific S-box is expressible through a single CA rule. The results show that genetic programming can find much smaller CA rules defining the same S-box up to the size  $7 \times 7$ .

## 2.2. Preliminaries

This section is devoted to introducing the preliminaries related to S-boxes' design and the evaluation metrics used to test their effectiveness. In addition, it includes a brief description of chaotic systems and the Rössler attractor, which is used in the design of our proposed S-box.

### 2.2.1. S-Box

An S-box, denoted as  $S$ , with dimensions  $n \times m$ , is a mapping defined as  $S : \{0, 1\}^n \rightarrow \{0, 1\}^m$ . It can be expressed as a search table with  $2^n$  rows,  $r_0, r_1, \dots, r_{2^n-1}$ , where  $r_i \in \{0, 1\}^m$  for  $i \in [0, 1, \dots, 2^n - 1]$  [32–34]. The mapping occurs by taking the  $i$ -th row, where  $i$  is the decimal value of the input, and then, the output is given by the  $r_i$  value. Depending on the size of  $n$ , this representation could have a large amount of rows; for example,

with  $n = 8$ , the table will have 256 rows. This is why another representation has been adopted. The input  $\{0, 1\}^n$  is split into two parts, keeping the bits sequence, let us say  $\{0, 1\}^n = \{0, 1\}^a \oplus \{0, 1\}^b$ , where  $\oplus$  is a concatenation. Then, rows in a table are represented by all the combinations generated by  $\{0, 1\}^a$  and columns by combinations of  $\{0, 1\}^b$ ; that is, we generate a table of size  $2^a \times 2^b$ , where the content of the cell will be the mapping associated with the input formed by its row with its column, which is,  $S(\{0, 1\}^a \oplus \{0, 1\}^b)$ . This form of S-box coding also contains all the possible combinations but with a reduced number of rows.

### 2.2.2. Criteria for Evaluating an S-Box

The evaluation of an S-box's strength hinges on its cryptographic characteristics, encompassing non-linearity, bijection, adherence to strict avalanche criterion (SAC), compliance with bit independence criterion (BIC), as well as linear and differential approximation probabilities. An ideal or near-optimal S-box attains the maximum values for these attributes. Furthermore, an S-box exhibiting elevated non-linearity and a minimal differential probability (DP) value is recognized as cryptographically strong [20].

#### Bijectivity

An  $n \times n$  S-box is said to be bijective if all its  $n$  Boolean functions have an equal number of 0 and 1. As a result, all  $2^n$  output values of the S-box are distinct and are also in the range of  $[0, 2^n - 1]$ . A Boolean function is 0/1 balanced if it satisfies Equation (1), where  $a_i \in \{0, 1\}$ ,  $(a_1, \dots, a_n) \neq (0, \dots, 0)$  and  $\text{hwt}()$  is the Hamming weight [35].

$$\text{hwt} \left( \sum_{i=1}^n a_i f_i \right) = 2^{n-1} \tag{1}$$

In other words, if the Hamming weight of the linear combination of all Boolean functions  $f_i$  of the designed  $n \times n$  S-box equals  $2^{n-1}$ , then the S-box is bijective.

#### Nonlinearity (NL)

Non-linearity is measured by how closely the S-box approximates a linear function; the S-box operation must avoid being a linear transformation from input to output, as it undermines the security of encryption methods. Furthermore, a greater degree of non-linearity suggests enhanced resistance against linear attacks. The non-linearity of a Boolean function  $f$  with  $n$  bits is computed using Equation (2), where  $W_f(z)$  represents the Walsh spectrum of the coordinate Boolean function  $f$ , which is measured as Equation (3), and  $t \cdot z$  is the dot product in a bit-by-bit way [22,35].

$$NL(f) = 2^{n-1} - \frac{1}{2} \left( \max_{z \in \{0,1\}^n} |W_f(z)| \right) \tag{2}$$

$$W_f(z) = \sum_{t \in \{0,1\}^n} (-1)^{f(t) \oplus t \cdot z} \tag{3}$$

#### Strict Avalanche Criterion (SAC)

The strict avalanche criterion (SAC) assesses how changes in the input bits affect the changes in the output bits of a cryptographic function. Moreover, SAC is an essential criterion because it measures the ability of the cryptographic function to introduce diffusion and confusion in data. This criterion requires that if an input has a single-bit flip, it should flip  $\frac{n}{2}$  bits out of  $n$  output bits [28]. A dependence matrix is calculated to test the SAC; Equation (4) describes how to calculate the dependence matrix [20].

$$\rho_{i,j}(f) = \sum_{x \in \{0,1\}^n} f_j(x) \oplus f_j(x \oplus e_i) \tag{4}$$

### Bit Independence Criterion (BIC)

The bit independence criterion was introduced by Webster and Tavares [36]; it necessitates that the output bits exhibit no correlation and that all input–output variables are mutually independent across all avalanche vectors [20]. Consider the Boolean functions  $f_1, f_2, \dots, f_8$ , which constitute an  $8 \times 8$  S-box. It has been observed that when the S-box satisfies the bit independence criterion (BIC), the Boolean function  $f_j \oplus f_k$  (where  $j \neq k$  and  $1 \leq j, k \leq 8$ ) exhibits a high degree of non-linearity and effectively meets the avalanche criterion. This ensures that if any individual input bit is inverted, the correlation coefficient between every pair of output bits will be close to zero.

### Differential Uniformity (DU)

A differential attack is a cryptanalysis technique where an attacker observes how small changes in input values result in differences in output values. The attacker tries to find patterns or relationships between these input–output differences to gain information about the cryptographic algorithm. Differential uniformity (DU) is a numerical measure that quantifies the maximum absolute difference between the probabilities of all possible input differences and their corresponding output differences.

- A lower differential uniformity indicates that the function has better diffusion properties, making it more resistant to differential attacks.
- A higher differential uniformity suggests that the function exhibits specific input–output patterns, which attackers can exploit in a differential attack.

In addition, DU helps in calculating the difference between input and output changes. If the difference is less (that is, the value of DU is less), an S-box can defy the differential cryptanalysis. Equation (5) is used to compute the DU value for an  $n \times n$  S-box [28].

$$DU = \max_{\Delta_m \neq 0, \Delta_n} (\#\{x \in X \mid S(x) \oplus S(x \oplus \Delta_x) = \Delta_y\}) \tag{5}$$

### Lineal Approximation Probability (LAP)

Block cipher algorithms aim to scramble input data bits thoroughly; a robust S-box contributes to this goal by offering a non-linear transformation from plaintext to ciphertext. On the other hand, linear cryptanalysis is an attacker’s attempt to uncover the weak connection between plaintext and ciphertext [28]. The effectiveness of this transformation is quantified by the linear approximation probability (LAP), as expressed in Equation (6).

$$LAP = \max_{m_x, m_y \neq 0} \left| \frac{\#\{x \in X \mid x \cdot m_x = S(x) \cdot m_y\}}{2^n} - \frac{1}{2} \right|, \tag{6}$$

where  $X$  is a set of all possible inputs  $x$ , whose cardinality is  $2^n$  for an  $n \times n$  S-box. Any S-box having a lower LP score tends to have better resistance to linear cryptanalysis [35].

#### 2.2.3. Rijndael S-Box

The Rijndael S-box is generated through a series of well-defined mathematical operations.

**Substitute Bytes:** In this step, each byte of the S-box is replaced by another byte based on a fixed lookup table. The lookup table is constructed using a mathematical transformation known as the finite field inversion. This transformation involves a combination of bitwise operations like substitution, addition, and multiplication in the finite field of Galois.

**Affine Transformation:** After the substitution step, an affine transformation is applied to each byte in the S-box. This transformation involves bitwise XOR operations with fixed constants. The purpose of this step is to further enhance the diffusion properties of the S-box, ensuring that small changes in the input result in significant changes in the output.

**Permutation:** The permutation step involves swapping the positions of the bytes in the S-box to create confusion and diffusion within the cipher. The permutation is designed to be efficient to compute and reversible, ensuring that the S-box can be easily inverted

during decryption. The combination of these steps results in a highly non-linear and secure S-box that is resistant to various cryptanalysis techniques.

### 2.2.4. Rössler Attractor

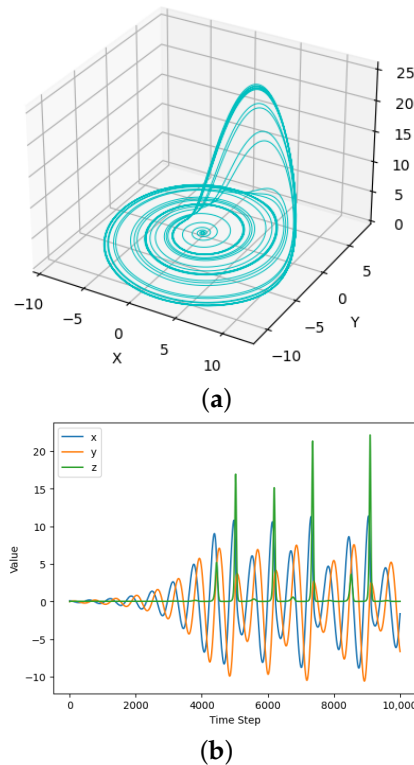

The Rössler attractor, discovered by the German biochemist and mathematician Otto Rössler in 1976, is an example of a chaotic dynamical system. This kind of system exhibits complex, unpredictable behavior. The Equations that define the Rössler system are (7)–(9), where  $x$ ,  $y$ , and  $z$  are the state variables of the system, and  $a$ ,  $b$ , and  $c$  are parameters that determine the behavior of the system that can form both a chaotic (but deterministic) and an ordered process in the three-dimensional phase space of the parameters [37,38]. On the other hand, it is often associated with chaotic or irregular motion, where the trajectory of a point in the three-dimensional space governed by the Rössler equations can display complex patterns that are highly sensitive to initial conditions,

$$\frac{dx}{dt} = -y - z \tag{7}$$

$$\frac{dy}{dt} = x + ay \tag{8}$$

$$\frac{dz}{dt} = bx - cz + xz, \tag{9}$$

where  $a = 0.2$ ,  $b = 0.2$ , and  $c = 5.7$ . The attractor’s trajectory in a three-dimensional space exhibits complex, swirling patterns and never settles into a stable equilibrium, as is shown in Figure 1a. This is a hallmark of chaotic systems, where small changes in initial conditions can lead to drastically different outcomes over time; in other words, tiny differences in the starting conditions can amplify over time and result in entirely different paths within the attractor, shown in Figure 1b.

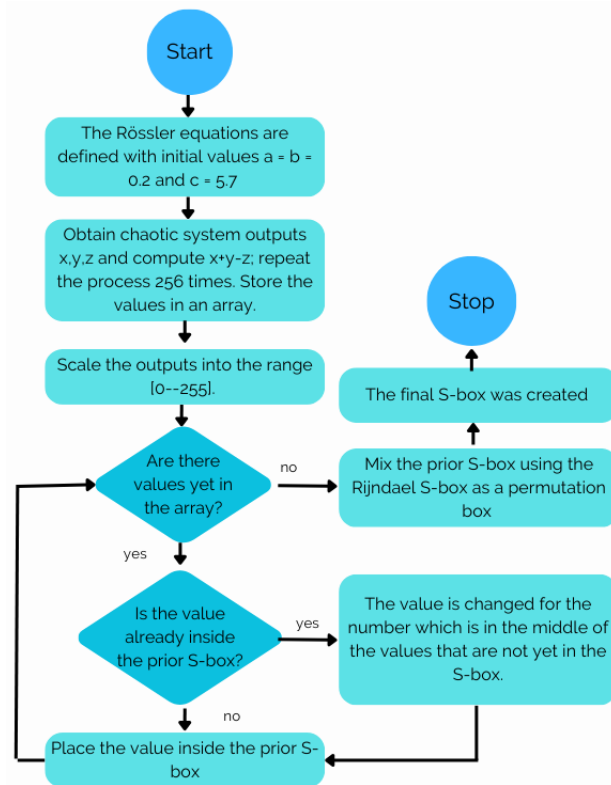

**Figure 1.** The complex and unpredictable behavior of the attractor with  $a = 0.2$ ,  $b = 0.2$ , and  $c = 5.7$  as initial conditions. (a) The Rössler attractor in 3D space. It is a well-known chaotic system; (b) a numerical simulation of the Rössler attractor that plots the values of three variables ( $x$ ,  $y$ , and  $z$ ) over a specified number of time steps.

### 3. Proposed S-Box Based on the Rössler Attractor

The suggested S-box is derived from the Rössler attractor and mixed with the Rijndael S-box as a permutation box. In this section, the process to generate S-boxes is explained.

The algorithm developed for creating an S-box using the dynamic behavior of the Rössler equations is shown in Figure 2. The initial steps focus on generating pseudo-random numbers, which are instrumental in defining the 256 values of the S-box. Subsequently, the final step involves introducing a layer of complexity by applying a transformation inspired by the Rijndael S-box to the generated numbers.

**Figure 2.** Flowchart for the proposed S-boxes. This diagram illustrates the process of creating S-boxes utilizing unpredictable behavior.

**Step 1.** The Rössler equations are defined with initial values of  $a = b = 0.2$  and  $c = 5.7$ . These values are chosen because the trajectories in the system’s phase space are highly sensitive to the initial conditions, and their solutions can exhibit complex and unpredictable behavior over time. In this case, it is a chaotic attractor, so the difference between the numbers obtained is minimal.

**Step 2.** The values for  $x$ ,  $y$ , and  $z$  are defined in such a way that the chaotic system can exhibit rich random characteristics.

**Step 3.** The values of new states are computed,  $x$  and  $y$  are added, and  $z$  is subtracted ( $x + y - z$ ); the process is repeated 256 times in order to create a sequence with numerical values.

**Step 4.** The values are transformed by scaling them between 0 and 255.

**Step 5.** A 256-value verification array, initially set to zero, is established to check that the values generated by the sequence are not repeated.

**Step 6.** The prior S-box is generated, assigning the sequence values to the positions from 0 to 255. Simultaneously, one is inserted into the already-filled values within the validation array. The sequence’s values are then checked for duplicates. If any duplicates are found, they are substituted with the value  $n$  within the validation array, marked as 0, where  $n$  is equivalent to the middle value.

**Step 7.** Mix the prior S-box using the Rijndael S-box as a permutation box, and the final S-box is obtained.

Through this process, we ensure that there are no repeated values within the S-box, thereby guaranteeing that our functions possess the property of being bijective.

#### 4. Results

An S-box plays a crucial role in introducing non-linearity and confusion in cryptographic operations; consequently, analyzing and evaluating the quality of a generated S-box is essential to designing secure and efficient cryptographic algorithms, particularly in symmetric-key ciphers. This section critically inspects the strength of the generated S-boxes 1 and 2, given in Tables 1 and 2, respectively.

##### 4.1. Bijectivity

Proposed S-boxes 1 and 2 have been confirmed to exhibit bijectivity, as all eight Boolean functions demonstrate balance, and their Hamming weight is 128. Additionally, the output values are in the range of [0, 255].

#### 4.2. Nonlinearity (NL)

The non-linearity scores for proposed S-boxes 1 and 2 are introduced in Table 3; for S-box 1, the minimum NL = 98, maximum NL = 106, average NL = 104.25, and for S-box 2, the minimum NL = 100, maximum NL = 106, average NL = 104 is achieved. High non-linearity measures ensure the ability of resisting attacks, such as linear cryptanalysis; also, Figure 3 demonstrates that the criterion is consistent with other S-boxes developed with chaos. For symmetric Boolean functions, the maximum non-linearity achieved is 112, and nonlinear values above 98 are considered good [20].

**Table 3.** The non-linearity values of proposed S-boxes 1 and 2. A greater degree of non-linearity leads to improved performance of an S-box against linear cryptanalysis attacks.

#### 4.3. Strict Avalanche Criterion (SAC)

Tables 4 and 5 exhibit the dependence matrix corresponding to proposed S-boxes 1 and 2. Comparing the average values obtained (0.5029 and 0.5002) to the theoretical value of 0.500 reveals a difference of 0.0029 for the first S-box and 0.0002 for the second S-box. Consequently, it can be affirmed that proposed S-boxes 1 and 2 meet the S-box Avalanche Criterion (SAC) requirement. An SAC value nearer to 0.5 is considered adequate [22].

**Table 4.** Results of the strict avalanche criterion for proposed S-box 1 with an average of 0.5029. This value refers to how a single-bit change in the input to an S-box should result in a highly unpredictable and “avalanching” change in the output bits.

4.4. Bit Independence Criterion (BIC)

The BIC values for no linearity are shown in Tables 6 and 7. Moreover, the average scores of BIC with respect to non-linearities are found to be 104 in S-box 1 and 103.92 in S-box 2. The obtained scores justify the good performance of proposed S-boxes for the bit independent criterion, and the comparison of BIC performance is made in Figure 4.

**Table 6.** Bit independence criterion with respect to non-linearity for proposed S-box 1. These values refer to the property that the output bits of an S-box should be statistically independent of each other.

4.5. Differential Uniformity (DU) and Differential Approximation Probability (DP)

Differential uniformity scores of proposed S-box 1 are shown in Table 8; it can be observed that proposed S-box 1 has 10 as the bigger value of DU, and consequently, 0.039 is the value of differential probability (DP). On the other hand, DU scores of proposed S-box 2 are shown in Table 9; the maximum DU value is 12, and consequently, 0.04687 is the value of differential probability (DP). The differential approximation probability value should be as low as possible to resist the Biham and Shamir cryptanalysis [35]. The lower scores confirm that the suggested S-box holds promise in resisting differential cryptanalysis attempts.

**Table 8.** I/O XOR differential distribution matrix for proposed S-box 1. Primarily low values (close to zero), indicate that changes in input bits lead to largely unpredictable changes in the output bits.

4.6. Lineal Approximation Probability (LAP)

The maximum values of LAP for proposed S-boxes are 0.127 and 0.123, which is pretty low, so we assert that it can resist linear cryptanalysis for the proposed S-boxes.

### 5. Comparative Analysis and Conclusions

This section provides an analysis of the evaluation results obtained by every test, and it is compared with other existent methods. We also provide our conclusions. The simulation of the proposed method to generate an S-box was developed in Python 3.8 on a system running Debian GNU/Linux 10 (buster), having 7.6 GB RAM, as well as an Intel Core i5 CPU 2.40 GHz processor. The proposed algorithm is designed to minimize execution time while conserving computational resources. The initial S-box generation takes 0.062942 s, and the subsequent permutation step for generating the final S-box requires only 0.011048 s.

#### 5.1. Comparative Analysis of the Proposed Algorithm

In the last several decades, researchers have explored various methods to create S-boxes resilient against cryptographic attacks [39]. A comparison of our proposed S-boxes with existing ones is made in Table 10 to evaluate not only its effectiveness but also its security features.

One of the main focuses in the design of S-boxes is non-linearity since it measures the relationship between the input and output values; the higher this measurement, the more difficult it will be for an attacker to predict or reverse its operations. Table 10 shows that there is an average non-linearity of 104 and 104.25, with the ideal value being 112. Another measurement is the SAC value that defines how much the outputs of the S-box change when a single input is compared to its original value. As a result, values close to the ideal of 0.5000 are obtained, having the one smallest difference in proposed S-box 2; this means that the S-box should have a highly unpredictable and non-linear response to variations in inputs. As a third criterion to evaluate, there is BIC-NL, which measures the extent to which the outputs of an S-box are statistically independent of each other when changes are applied to the inputs; the higher this value, the more the behavior of the S-box is considered unpredictable and safer. The S-box in the proposed design in this parameter, proposed S-box 1, performed better than the other S-boxes analyzed. The DU of proposed S-box 1 is 10, which is better than S-box 2. Both fall within the range of values obtained by chaotic methods but develop worse than other known S-boxes, such as AES, Gray, and APA, which have uniform values of 8, 4, and 4, respectively. According to the linear cryptanalysis of Matsui, the linear approximation probability should be kept as low as possible, which has a value of 0.127 and 0.123, respectively, for our S-boxes. The proposed S-box had a higher score of LP and DP than some S-boxes, showing that our method had advantages in resisting the attacks of differential cryptanalysis and linear cryptanalysis.

Table 11 displays the results of S-boxes created using non-chaotic methods. It is evident that superior results in terms of non-linearity are achieved. Notably, the proposed S-box outperforms these ones in terms of SAC and linear approximation probability. AES S-box, while exhibiting excellent values, is static. Having adaptability is an advantage

of a dynamic S-box, allowing it to adjust its substitution rules based on varying input conditions, thereby enhancing its resistance to various forms of cryptanalysis.

In addition, the presence of multiple attractors in the Rössler system is particularly interesting and depends on the values of  $a$ ,  $b$ , and  $c$ . Depending on how these parameters are configured, the system can exhibit different dynamical behaviors, including the presence of chaotic attractors, periodic attractors, and other behaviors.

Secondly, the Rössler attractor for the generation of chaotic sequences is beneficial since the equations that describe it are three-dimensional; this creates greater complexity for the system to represent complex and chaotic dynamic systems compared to a one-dimensional system. For the generation of S-boxes, a system that exhibits greater unpredictability is sought. Compared to the Lorenz system, the equations that define the Rössler system are simpler; this allows the box generation process to have less computational complexity and to be more accessible to model and interpret.

## 5.2. Conclusions

This research paper introduces a straightforward and highly effective method for constructing S-boxes utilizing the Rössler attractor. The proposed method is resource-efficient, characterized by its simple design and efficiency, while meeting all required security parameters. We evaluated and analyzed two cases to confirm their cryptographic properties, applying standard criteria. Notably, all requirements were successfully met. They can exhibit different dynamic behaviors depending on how parameters  $a$ ,  $b$ , and  $c$  are configured in the Rössler system. In this article, the parameters were defined as  $a = b = 0.2$  and  $c = 5.7$  since the system's phase space trajectories are highly sensitive to the initial conditions and behave unpredictably in the long term.

Moreover, the complexity and non-linearity inherent to the Rössler attractor can make brute force attacks difficult since the relationship between the key and the output of the S-box is not direct or predictable. The design makes statistical attacks difficult, which helps in that there is greater robustness against differential and linear cryptanalysis. As a future perspective, the generation of these boxes could be incorporated into an encryption/decryption system. In this scenario, the values of  $x$ ,  $y$ , and  $z$  will be determined by transforming the user-provided key. This encryption process can be applied to both images and files, depending on how the system is designed. Finally, an additional application can involve its deployment on mobile devices, given its effectiveness, as an encryption tool to safeguard data privacy and authenticity during transmissions or communications.
